The grey Wesersandstein from Germany is a typical triassic feldspatic sandstone containing some secondary modified lenses with lower density and interesting mineralogical features. These lenses contain some secondary pseudomorphs of quartz after halite.

These lenses, from 1mm to 1cm in the sandstone are interpreted by a diagenetic process during which some original NaCl formation is replaced by other sodium containing minerals like Albite. Also Halite is replaced by SiO₂ (release from the alteration of feldspars). Figure 1 shows a typical slab with the various secondary filled lenses. The grey Wesersandstein is actually used as building and construction material for many applications.

Fig. 1: Slab of grey Wesersandstein with various secondary filled lenses with lower density

Due to this fact different grains and crystals of quartz occur in the feldspar.

1. Original quartz grains of the sandstone
2. Secondary authigenic quartz crystals
3. Pseudomorphs of quartz after halite-crystal (hexaedric habit)
4. Typical etching cavities due to weathering effects

The following images show the different quartz habits and formations in the grey Wesersandstein

formation.

In the performed investigations for investigation of probable usage of Wesersandstein as a potential storage material, these different quartz crystals can have different geochemical and geomechanical properties. The formation and habit also differs from their varying origin. Almost rounded quartz grains in the sandstone, newly crystallized idiomorphic quartz and also pseudocubic and pseudomorphous quartz. Some newly formed quartz crystals show already etching pits as their faces are already under the influence of starting dissolution.
